Abstract

We present SGDPLL($T$), an algorithm that solves (among many other problems) probabilistic inference modulo theories, that is, inference problems over probabilistic models defined via a logic theory provided as a parameter (currently, equalities and inequalities on discrete sorts). While many solutions to probabilistic inference over logic representations have been proposed, SGDPLL($T$) is the only one that is simultaneously (1) lifted, (2) exact and (3) modulo theories, that is, parameterized by a background logic theory. This offers a foundation for extending it to rich logic languages such as data structures and relational data. By lifted, we mean that our proposed algorithm can leverage first-order representations to solve some inference problems in constant or polynomial time in the domain size (the number of values that variables can take), as opposed to exponential time offered by propositional algorithms.

1 Introduction

Uncertainty representation, inference and learning are important goals in Artificial Intelligence. In the past few decades, neural networks and graphical models have made much progress towards those goals, but even today their main methods can only support very simple types of representations (such as tables and weight matrices) that exclude logical constructs such as relations, functions, arithmetic, lists and trees. Moreover, such representations require models involving discrete variables to be specified at the level of their individual values, making generic algorithms expensive for finite domains and impossible for infinite ones.

For example, consider the following conditional probability distributions, which would need to be either automatically expanded into large tables (a process called propositionalization), or manipulated in a manual, ad hoc manner, in order to be processed by mainstream neural networks or graphical model algorithms:

- $P(x > 10 \mid y \neq 98 \vee z \leq 15) = 0.1$, for $x, y, z \in \{1, \ldots, 1000\}$
- $P(x \neq Bob \mid friends(x, Ann)) = 0.3$

The Statistical Relational Learning [Getoor and Taskar, 2007] literature offered more expressive languages but relied on conversion to conventional representations to perform inference, which can be very inefficient. To counter this, lifted inference [Poole, 2003; de Salvo Braz, 2007] offered solutions for efficiently processing logically specified models, but with languages of limited expressivity (such as function-free ones) and algorithms that are hard to extend. Probabilistic programming [Goodman et al., 2012] has offered inference on full programming languages, but relies on approximate methods on the propositional level.

We present SGDPLL($T$), an algorithm that solves (among many other problems) probabilistic inference on models defined over logic representations. Importantly, the algorithm is agnostic with respect to which particular logic theory is used, which is provided to it as a parameter. In this paper, we use the theory consisting of equalities over finite discrete types, and inequalities over bounded integers, as an example. However, SGDPLL($T$) offers a foundation for extending it to richer theories involving relations, arithmetic, lists and trees. While many algorithms for probabilistic inference over logic representations have been proposed, SGDPLL($T$) is distinguished by being the only existing solution that is simultaneously (1) lifted, (2) exact and (3) modulo theories.

SGDPLL($T$) is a generalization of the Davis-Putnam-Logemann-Loveland (DPLL) algorithm for solving the satisfiability problem. SGDPLL($T$) generalizes DPLL in three ways: (1) while DPLL only works on propositional logic, SGDPLL($T$) takes (as mentioned) a logic theory as a parameter; (2) it solves many more problems than satisfiability on boolean formulas, including summations over real-typed expressions, and (3) it is **symbolic**, accepting input with free variables (which can be seen as constants with unknown values) in terms of which the output is expressed.

Generalization (1) is similar to the generalization of DPLL made by Satisfiability Modulo Theories (SMT) [Barrett et al., 2009; de Moura et al., 2007; Ganzinger et al., 2004], but SMT algorithms require only satisfiability solvers of their theory parameter to be provided, whereas SGDPLL($T$) may require solvers for harder tasks (including model counting) that depend on the theory, including **symbolic model counters**, i.e., Figures 1 and 2 illustrate how both DPLL and SGDPLL($T$) work and highlight their similarities and differences.
2 Intuition: DPLL, SMT and SGDPLL(T)

![Example of DPLL's search tree for the existence of satisfying assignments.](image)

Figure 1: Example of DPLL’s search tree for the existence of satisfying assignments. We show the full tree even though the search typically stops when the first satisfying assignment is found.

![Algorithm 1](image)

Algorithm 1 A version of the DPLL algorithm.

**DPLL(F)**

- **F:** a formula in CNF.
- **simplify:** simplifies boolean formulas given a condition (e.g., `simplify(x ∧ y | ¬y) = FALSE`)

1. if `F` is a boolean constant
2. return `F`
3. else `v ←` pick a variable in `F`
4. `Sol_1 ← DPLL(simplify(F | v))`
5. `Sol_2 ← DPLL(simplify(F | ¬v))`
6. return `Sol_1 ∨ Sol_2`

Satisfiability Modulo Theories (SMT) algorithms [Barrett et al., 2009; de Moura et al., 2007; Ganzinger et al., 2004] generalize DPLL and can determine the satisfiability of a Boolean formula expressed in first-order logic, where some function and predicate symbols have additional interpretations. Examples of predicates include equalities, inequalities, and uninterpreted functions, which can then be evaluated using rules of real arithmetic. SMT algorithms condition on the literals of a background theory `T`, looking for a truth assignment to these literals that satisfies the formula. While a SAT solver is free to condition on a proposition, assigning it to either `TRUE` or `FALSE` regardless of previous choices (truth values of propositions are independent of each other), an SMT solver needs to also check whether a choice for one literal is consistent with the previous choices for others, according to `T`. This is done by a theory-specific model checker provided to the SMT algorithm as a parameter.

SGDPLL(T) is, like SMT algorithms, modulo theories but further generalizes DPLL by being **symbolic and quantifier-parametric** (thus “Symbolic Generalized DPLL(T)”). These three features can be observed in the prob-
lem being solved by SGDPLL(T) in Figure 2:
\[
\sum_{x,z \in \{1, \ldots, 100\}} (\text{if } x > y \land y \neq 5 \text{ then } 0.1 \text{ else } 0.9) \\
\times (\text{if } z < y \land y < 3 \text{ then } 0.4 \text{ else } 0.6)
\]

In this example, the problem being solved requires more than propositional logic theory since equality, inequality and other functions are involved. The problem’s quantifier is a \(\exists\), other functions are involved. The problem’s quantifier is a \(\exists\) than propositional logic theory since equality, inequality and other functions are involved. The problem’s quantifier is a \(\exists\), the problem being solved requires more than propositional logic theory since equality, inequality and other functions are involved. The problem’s quantifier is a \(\exists\), other functions are involved. The problem’s quantifier is a \(\exists\)

Quantifier-parametric Satisfiability can be seen as computing the value of an existentially quantified formula; the existential quantifier can be seen as an indexed form of disjunction, so we say it is \(\text{based}\) on disjunction. SGDPLL(T) generalizes SMT algorithms with respect to the problem being solved by computing expressions quantified by \(\text{any quantifier}\) \(\bigoplus\) \(\text{based on an associative commutative operation}\) \(\bigoplus\). Examples of \((\bigoplus, +, \cdot)\) pairs are \((\forall, \land), (\exists, \lor), (\sum, +), (\Pi, \times)\). Therefore SGDPLL(T) can solve not only satisfiability (since disjunction is associative commutative), but also validity (using the \(\forall\) quantifier), sums, products, model counting, weighted model counting, maximization, and many more.

Modulo Theories SMT generalizes the propositions in SAT to literals in a given theory \(T\), but the theory connecting these literals remains that of boolean connectives. SGDPLL(T) takes a theory \(T = (T_C, T_E)\), composed of a \(\text{constraint theory}\) \(T_C\) and an \(\text{input theory}\) \(T_E\). DPLL propositions are generalized to literals in \(T_C\) in SGDPLL(T), whereas the boolean connectives are generalized to functions in \(T_C\). In the example above, \(T_C\) is the theory of inequalities on bounded integers, whereas \(T_E\) is the theory of \(+, \times\), boolean connectives and \(\text{if then else}\). \(T_C\) is used simply for the simplifications after conditioning, which takes time at most linear in the input expression size.

Symbolic Both SAT and SMT can be seen as computing the value of an existentially quantified formula in which \(\text{all variables}\) are quantified, and which is always equivalent to either \(\text{true}\) or \(\text{false}\). SGDPLL(T) further generalizes SAT and SMT by accepting quantifications over \(\text{any subset}\) of the variables in its input expression (including the empty set). The non-quantified variables are \(\text{free variables}\), and the result of the quantification will typically depend on them. Therefore, SGDPLL(T)’s output is a \(\text{symbolic}\) expression in terms of free variables. Section 3 shows an example of a symbolic solution.

\section{T-Problems and T-Solutions}
SGDPLL(T) receives a \(T\)-\text{problem} (or, for short, simply a \text{problem}) of the form
\[
\bigoplus_{x_1:C_1} \ldots \bigoplus_{x_m:C_m} E,
\]
where, for each \(i = 1, \ldots, m, x_i\) is an \(\text{index variable}\) quantified by \(\bigoplus\) and subject to constraint \(C_i\) in \(T_C\), and \(E\) an expression in \(T_E\). \(C_i\) is assumed to be equivalent to a conjunction of literals in \(T_C\). There may be \(\text{free variables}\), that is, variables that are not quantified, present in both the constraints and \(E\). An example of a problem is
\[
\sum_{x:3 \leq x \land x \leq y} \text{if } x > 4 \text{ then } y \text{ else } 10 + z,
\]
for \(x, y\) bounded integer variables in, say, \(\{1, \ldots, 20\}\).

A \(T\)-\text{solution} (or, for short, simply a \text{solution}) to a problem is a quantifier-free expression in \(T_C\) equivalent to the problem. It can be an \text{unconditional solution}, containing no literals in \(T_C\), or a \text{conditional solution} of the form
\[
\text{if } L \text{ then } S_1 \text{ else } S_2,
\]
where \(L\) is a literal in \(T_C\) and \(S_1, S_2\) are two solutions (either conditional or unconditional). Note that, in order for the solution to be equivalent to the problem, only variables that were free (not quantified) can appear in the literal \(L\). In other words, a solution can be seen as a decision tree on literals, with literal-free expressions in the leaves, such that each leaf is equivalent to the original problem, provided that the literals on the path to it are true. For example, the problem
\[
\sum_{x:1 \leq x \land x \leq 10} \text{if } y > 2 \land w > y \text{ then } y \text{ else } 4
\]
has an equivalent conditional solution
\[
\text{if } y > 2 \text{ then } \text{if } w > y \text{ then } 10y \text{ else } 40 \text{ else } 40.
\]

\section{SGDPLL(T)}
In this section we provide the details of SGDPLL(T), described in Algorithm 2 and exemplified in Figure 2. We first give an informal explanation guided by examples, and then provide a formal description of the algorithm.

\subsection{Informal Description of SGDPLL(T)}

\textbf{Base Case Problems}

A problem is in \textbf{base case 0} if and only if \(m = 1, E\) contains no literals in \(T_C\) and \(C\) is in a \textbf{base form} specific to the theory \(T\), which its solver must be able to recognize.

In our running example, we take a slight variant of \textbf{difference arithmetic} [de Moura et al., 2007], with atoms of the form
\[
x < y \text{ or } x \leq y + c,\text{ where } c \text{ is an integer constant. Strict inequalities } x < y + c \text{ can be represented as } x \leq y + c - 1 \text{ and the negation of } x \leq y + c \text{ is } y \leq x - c - 1. \text{ From now on, we shorten } a \leq x \land x \leq b \text{ to } a \leq x \leq b.
\]

The base case for difference arithmetic is
\[
\sum_{x:y+1 \leq x \leq z-3} y^2 +
\]
4x^3. When \( l \leq u \), Faulhaber’s formula [Knuth, 1993] allows us to compute a new polynomial \( E' \) (in the variables other than \( x \)) equivalent to the problem. Moreover, this can be done (a little surprisingly) in time only dependent in the degree of the polynomial \( E \), not on the domain size of \( x \) or the distance \( u - l \). \(^1\) If \( l \leq u \) is false, there are no values of \( x \) satisfying the constraint, and the problem results in 0. Therefore, the solution is the conditional if \( l \leq u \) then \( E' \) else 0.

A base case \( 1 \) problem is such that \( m > 1 \) and \( \bigoplus_{x \in C_m} E \) satisfies base case 0, yielding solution \( S \). In this case, we reduce the problem to the simpler

\[
\bigoplus_{x_1 : C_1} \cdots \bigoplus_{x_{m-1} : C_{m-1}} S.
\]

Non-Base case Problems

For non-base cases, SGDPLL(\( T \)) mirrors DPLL, by selecting a splitter literal to split the problem on, generating two simpler problems. This eventually leads to base case problems.

The splitter literal \( L \) can come from either the expression \( E \), to bring it closer to being literal-free, or from \( C_m \), to bring it closer to satisfying the base form prerequisites. We will see examples shortly.

Once the splitter literal \( L \) is chosen, it splits the problem in two possible ways: if \( L \) does not contain any of the indices \( x_i \), it causes an if-splitting in which \( L \) is the condition of an if then else expression and the two simpler subproblems are its then and else clauses; if \( L \) contains at least one index, it causes a quantifier-splitting based on the latest of the indices it contains.

For an example of an if-splitting on a literal coming from \( C_m \), consider the problem

\[
\sum_{z} \sum_{x : y \leq x \land 3 \leq x \land x \leq 10} y^2.
\]

This is not a base case because the constraint includes two lower bounds for \( x \) (\( y \) and 3), which are not redundant because we do not know which one is the smallest. We can however reduce the problem to base case ones by splitting the problem according to \( y < 3 \):

\[
\text{if } y < 3 \text{ then } \sum_{z} \sum_{x : 3 \leq x \leq 10} y^2 \text{ else } \sum_{z} \sum_{x : y \leq x \leq 10} y^2.
\]

For another example of an if-splitting, but on a literal coming from \( E \) this time, consider

\[
\sum_{z} \sum_{x : 3 \leq x \leq 10} \text{if } y > 4 \text{ then } y \text{ else } 10.
\]

This is not a base case because \( E \) is not literal-free. However, splitting on \( y > 4 \) reduces to

\[
\text{if } y > 4 \text{ then } \sum_{z} \sum_{x : 3 \leq x \leq 10} y \text{ else } \sum_{z} \sum_{x : 3 \leq x \leq 10} 10,
\]

containing two base cases.

\(^1\)This takes a number of steps, which we omit for lack of space, but it is not hard to do.

For an example of quantifier-splitting on a literal coming from \( E \), consider this problem in which the splitter literal contains at least one index (here it contains two, \( x \) and \( z \)):

\[
\sum_{x : 3 \leq x \leq 10} \sum_{z} \text{if } x > 4 \text{ then } y \text{ else } 10 + z.
\]

In this case, we cannot simply move the literal outside the scope of the sum in its latest index \( x \). Instead, we add the literal and its negation to the constraint on \( x \), in two new subproblems:

\[
= \left( \sum_{x : 3 \leq x \leq 10} \sum_{z} y \right) + \left( \sum_{x : 3 \leq x \leq 10} \sum_{z} 10 + z \right).
\]

In this example, the two sub-solutions are unconditional polynomials, and their sum results in another unconditional polynomial, which is a valid solution. However, if at least one of the sub-solutions is conditional, their direct sum is not a valid solution. In this case, we need to combine them with a distributive transformation of \( \oplus \) over \( \text{if then else} \):

\[
(\text{if } x < 4 \text{ then } y^2 \text{ else } z) + (\text{if } y > z \text{ then } 3 \text{ else } x)
\]

\[
\equiv \text{if } x < 4 \text{ then } y^2 + (\text{if } y > z \text{ then } 3 \text{ else } x)
\]

\[
\text{else } z + (\text{if } y > z \text{ then } 3 \text{ else } x)
\]

\[
\equiv \text{if } x < 4 \text{ then } y^2 + 3 \text{ else } y^2 + x
\]

\[
\text{else } y > z \text{ then } z + 3 \text{ else } z + x.
\]

4.2 Formal Description of SGDPLL(\( T \))

We now present a formal version of the algorithm. We start by specifying the basic tasks the given \( T \)-solver is required to solve, and then show can we can use it to solve any \( T \)-problems.

Requirements on \( T \)-solver

To be a valid input for SGDPLL(\( T \)), a \( T \)-solver \( S_T \) for theory \( T = (T_L, T_C) \) must solve two tasks:

- Given a problem \( \bigoplus_{x \in C} E \), \( S_T \) must be able to recognize whether \( C \) is in base form and, if so, provide a solution base(\( \bigoplus_{x \in C} E \)) for the problem.
- Given a conjunction \( C \) not in base form, \( S_T \) must provide a tuple split(\( C \)) = \( (L, C_L, C_{-L}) \) such that \( L \in T_C \) and conjunctions \( C_L \) and \( C_{-L} \) are smaller than \( C \) and satisfy \( L \Rightarrow (C \Leftrightarrow C_L) \land \lnot L \Rightarrow (C \Leftrightarrow C_{-L}) \).

The algorithm is presented in Figure 2. Note that it does not depend on difference arithmetic theory, but can use a solver for any theory satisfying the requirements above. Note also that conditional solution may contain redundant literals, and that optimizations such as unit propagation and watch literals can be employed. These issues can be addressed but we omit the details for lack of space.

If the \( T \)-solver implements the operations above in polynomial time in the number of variables and constant time in the domain size (the size of their types), then SGDPLL(\( T \)), like DPLL, will have time complexity exponential in the number of literals and, therefore, in the number of variables, and
be independent of the domain size. This is the case for the solver for difference arithmetic and will be typically the case for many other solvers.

5 Probabilistic Inference Modulo Theories

Let $P(X_1 = x_1, \ldots, X_n = x_n)$ be the joint probability distribution on random variables $\{X_1, \ldots, X_n\}$. For any tuple of indices $t$, we define $X_t$ to be the tuple of variables indexed by the indices in $t$, and abbreviate the assignments $(X = x)$ and $(X_t = x_t)$ by simply $x$ and $x_t$, respectively. Let $l$ be the tuple of indices in $\{1, \ldots, n\}$ but not in $t$.

The marginal probability distribution of a subset of variables $X_q$ is one of the most basic tasks in probabilistic inference, defined as $P(x_q) = \sum_{x_l} P(x)$ which is a summation on a subset of variables occurring in an input expression, and therefore solvable by SGDPLL(T).

If $P(X = x)$ is expressed in the language of input and constraint theories appropriate for SGDPLL(T) (such as the one shown in Figure 2), then it can be solved by SGDPLL(T), without first converting its representation to a much larger one based on tables. The output will be a summation-free expression in the assignment variables $x_q$ representing the marginal probability distribution of $X_q$.

Other probabilistic inference problems can be equally solved by SGDPLL(T). Belief updating consists of computing the posterior probability of $X_q$ given evidence on $X_e$, which is defined as $P(x_q | x_e) = P(x_q, x_e) / P(x_e)$ which be computed with two applications of SGDPLL(T), one for the marginal $P(x_q, x_e)$ and another for $P(x_e)$.

Applying SGDPLL(T) in the manner above does not take advantage of factorized representations of joint probability distributions, a crucial aspect of efficient probabilistic inference. However, it can be used as a basis for an algorithm, Symbolic Generalized Variable Elimination modulo theories (SGVE(T)) [Zhang and Poole, 1994] for graphical models, that exploits factorization. Suppose $P(x)$ is represented as a product of real-valued functions (called factors) $f_i(x) = f_i(x_{t_1}) \times \cdots \times f_m(x_{t_m})$ where $q$ and $t_i$ are tuples. Let $q$ be the product of all factors in which $x_i$ does not appear, $h$ be the product of all factors in which $x_i$ does appear, and $b$ be the tuple of indices of variables other than $x_i$ appearing in $h$. Then we rewrite the above as

$$
\sum_{x_i} g(x_i) \sum_{x_i} h(x_i, x_b) = \sum_{x_i} g(x_i) h'(x_b)
$$

where $h'$ is a summation-free factor computed by SGDPLL(T) and equivalent to the innermost summation. We now have a problem of the same type as originally, but with one less variable, and can proceed until all variables in $x_q$ are eliminated. The fact that SGDPLL(T) is symbolic allows us to compute $h'$ without iterating over all values to $x_i$.

SGDPLL(T) contributes to the symbolic connectionist literature by providing a way to incorporate logic representations to systems dealing with uncertainty. If the variables and

data used by SGDPLL(T) in a given system are of a sub-symbolic, distributed nature, then this system will exhibit advantages of connectionism, observed on logic representations instead of simpler propositional representations.

6 Evaluation
We did a very preliminary comparison of SGDPLL(T)-based SGVE(T), using an implementation of an equality theory (\(\neq\), \(\neq\) literals only) symbolic model counter, to the state-of-the-art probabilistic inference solver variable elimination and conditioning (VEC) [Gogate and Dechter, 2011], on randomly generated probabilistic graphical models based on equalities formulas, on a Intel Core i7 notebook.

We ran both SGVE(T) and VEC on a random graphical model with 10 random variables, 5 factors, with formulas of depth and breadth (number of arguments per sub-formula) 2 for random connectives \(\lor\) and \(\land\). SGVE(T) took 1.5 seconds to compute marginals for all variables (unsurprisingly, irrespective of domain size). We grounded this model for domain size 16 to provide the table-based input required by VEC, which took then 30 seconds to compute all marginals. The largest grounded table given to VEC as input had 6 random variables and therefore around 16 million entries.

7 Related work
SGDPLL(T) is related to many different topics in both logic and probabilistic inference literature, besides the strong links to SAT and SMT solvers.

SGDPLL(T) is a lifted inference algorithm [Poole, 2003; de Salvo Braz, 2007; Gogate and Domingos, 2011], but the proposed lifted algorithms so far have concerned themselves only with relational formulas with equality. We have not yet developed a relational model counter but presented one or inequalities, the first in the lifted inference literature.

SGDPLL(T) generalizes several algorithms that operate on mixed networks [Mateescu and Dechter, 2008] – a framework that combines Bayesian networks with constraint networks, but with a much richer representation.

8 Conclusion and Future Work
We have presented SGDPLL(T) and its derivation SGVE(T), the first algorithms formally able to solve a variety of model counting problems (including probabilistic inference) modulo theories, that is, capable of being extended with theories for richer representations than propositional logic, in a lifted and exact manner.

Future work includes additional theories of interest mainly among them those for uninterpreted relations (particularly multi-arity functions) and arithmetic; modern SAT solver optimization techniques such as watched literals and unit propagation anytime approximation schemes that offer guaranteed bounds on approximations that converge to the exact solution.
